(Dated: April 19, 2025)

We present experimentally testable predictions derived from the Universe Ontology (UO) theoretical framework, specifically focusing on Quantum XOR Causal Invariance phenomena. The UO theory, based on fundamental FLIP-XOR-SHIFT operations, unifies quantum and classical physical descriptions through information field dynamics. We identify four key experimental predictions: (1) quantum causal invariance under XOR-SHIFT transformations, experimentally verifiable through modified quantum delayed-choice setups; (2) non-local XOR correlation preservation in entangled systems, testable via specific measurement protocols on Bell-type experiments; (3) quantum phase transition signatures at critical XOR-SHIFT coupling, observable in artificial quantum systems; and (4) phase-dependent quantum coherence oscillations during sequential XOR operations. These predictions enable critical experimental assessment of the UO framework across multiple quantum physics domains, revealing fundamental connections between information operations and physical reality.

INTRODUCTION

The unification of quantum and classical physics remains one of the most significant challenges in theoretical physics. The Universe Ontology (UO) theory [1] proposes a novel approach to this problem by postulating that fundamental information operations—specifically XOR and SHIFT—form the underlying basis for all physical phenomena. While the theoretical framework has demonstrated mathematical consistency and explanatory power, empirical verification is essential for scientific validation.

This paper focuses on experimentally testable predictions derived from the Quantum XOR Causal Invariance theory [2], a key component of the UO framework that describes causal relationships in quantum systems through XOR operations. We present four specific experimental predictions, each targeting different aspects of quantum physics, and describe experimental protocols that could verify or falsify these predictions.

THEORETICAL BACKGROUND

The Universe Ontology theory posits that the universe can be described as an information system evolving through two fundamental operations:

1. XOR (\oplus): An operation representing information difference
2. SHIFT (S): An operation representing state transition

The core state evolution equation is:

$$\mathcal{U}^{t+1} = \Omega_Q^t \oplus \text{SHIFT}(\Omega_Q^t \oplus \text{SHIFT}(\Omega_Q^t)) \quad (1)$$

Where \mathcal{U} represents the universe state, Ω_Q represents the quantum domain, and t is the evolution parameter.

The Quantum XOR Causal Invariance theory extends this framework to quantum systems, defining causal relationships as:

$$C(q_a, q_b) = q_a \oplus \text{SHIFT}(q_b) \quad (2)$$

Where q_a and q_b are quantum events, and $C(q_a, q_b)$ represents the causal strength between them.

EXPERIMENTAL PREDICTIONS

Quantum Causal Invariance Under XOR-SHIFT Transformations

The UO theory predicts that quantum causal relationships remain invariant under a specific class of transformations:

$$T_{\alpha,\beta}(q) = \alpha \cdot q \oplus \beta \cdot \text{SHIFT}(q) \quad (3)$$

Where $\alpha \oplus \beta = 1$.

Experimental Prediction 1: In a modified quantum delayed-choice experiment, applying the transformation $T_{\alpha,\beta}$ to the initial quantum state will preserve causal measurement outcomes when $\alpha \oplus \beta = 1$, but alter them when this condition is violated.

Experimental Protocol: We propose a modified Wheeler's delayed-choice experiment using polarization-entangled photons. The transformation $T_{\alpha,\beta}$ can be implemented using a combination of wave plates and polarization-dependent delay lines. By varying α and β values and measuring interference patterns, experimenters can directly test the invariance condition.

Expected observation: When $\alpha \oplus \beta = 1$, interference patterns will remain unchanged despite the transformation; when $\alpha \oplus \beta \neq 1$, pattern distortions will appear proportional to the deviation from equality.

Non-local XOR Correlation Preservation

The UO theory predicts that when quantum systems undergo XOR operations, certain correlation properties remain preserved even in non-local settings.

Experimental Prediction 2: In an entangled two-particle system, applying local XOR operations with reference states will preserve a specific set of non-local correlations, measurable through an extended Bell-type inequality:

$$|\langle A_1 \oplus R_1, B_1 \rangle + \langle A_1 \oplus R_1, B_2 \rangle + \langle A_2 \oplus R_2, B_1 \rangle - \langle A_2 \oplus R_2, B_2 \rangle| \leq 2 \quad (4)$$

Where A_i, B_i are measurement settings and R_i are reference states.

Experimental Protocol: Using entangled photon pairs, implement XOR operations through polarization rotations combined with reference beams. Measure correlations across different settings to verify whether the extended inequality holds.

Expected observation: The inequality will be violated in standard quantum mechanical systems, but specific correlation terms involving XOR operations will show invariance properties not predicted by standard quantum mechanics.

Quantum Phase Transitions at Critical XOR-SHIFT Coupling

The UO theory predicts the existence of phase transitions in quantum systems at critical values of XOR-SHIFT coupling strength.

Experimental Prediction 3: In a controlled quantum many-body system, a phase transition will occur at a critical XOR-SHIFT coupling strength λ_c , characterized by:

$$E(\lambda) \propto |\lambda - \lambda_c|^\nu \quad (5)$$

Where E is system energy, λ is coupling strength, and $\nu \approx 1.615$ is a universal critical exponent derived from the UO theory.

Experimental Protocol: Implement in trapped ion or superconducting qubit systems, where interactions can be precisely controlled. Gradually increase the coupling between XOR operations and SHIFT operations, monitoring system energy and correlation length.

Expected observation: A sharp phase transition at λ_c with critical exponent approximately 1.615, distinguishable from other known universality classes.

Phase-Dependent Quantum Coherence Oscillations

The UO theory predicts distinctive oscillation patterns in quantum coherence during sequential XOR operations.

Experimental Prediction 4: When a quantum system undergoes sequential XOR operations with controlled phase shifts, coherence will oscillate according to:

$$C(n) = C_0 \cdot \cos(n\theta + \phi_0) \cdot e^{-n/n_0} \quad (6)$$

Where $C(n)$ is coherence after n operations, θ is the phase rotation angle between operations, and n_0 is the coherence decay constant.

Experimental Protocol: Using single photons or superconducting qubits, implement a series of XOR operations interspersed with controlled phase rotations. Measure coherence as a function of operation number and phase rotation angle.

Expected observation: Coherence will follow the predicted oscillation pattern with specific dependence on phase rotation angles unique to XOR operation properties.

DISCUSSION

These four experimental predictions provide distinct signatures of the Universe Ontology theoretical framework that can be tested using current or near-term quantum experimental capabilities. They target different aspects of quantum physics: causal structures, non-local correlations, phase transitions, and coherence dynamics.

The predictions are specifically designed to differentiate UO theory from conventional quantum mechanics and other competing theories. In particular:

1. The specific form of invariance under XOR-SHIFT transformations is unique to the UO framework
2. The non-local correlation preservation under XOR operations differs from standard Bell inequality predictions
3. The critical exponent at the predicted phase transition would serve as a distinctive signature
4. The coherence oscillation pattern under sequential XOR operations provides a clear fingerprint of the theory

These experiments collectively form a comprehensive test suite for the foundation of the Universe Ontology

theory. They are designed to be independently verifiable across different quantum experimental platforms, ensuring robust validation or falsification of the theory's core predictions.

CONCLUSION

We have presented four specific, experimentally testable predictions derived from the Universe Ontology theoretical framework. These predictions, centered around the concept of Quantum XOR Causal Invariance, offer concrete opportunities to validate or falsify key aspects of the theory. The proposed experimental protocols are feasible with current technology, providing a practical path toward empirical assessment of this novel theoretical approach to unifying quantum and classical physics.

Should these predictions be experimentally confirmed, they would provide strong evidence for the role of fundamental information operations in the structure of phys-

ical reality, potentially opening new avenues for understanding quantum phenomena and advancing quantum technologies.
